Hemangiopericytoma is a rare mesenchymal tumor, considered as a subtype of soft tissue sarcomas with an incidence of 3.77/10.000.000 cases. Intracranial hemangiopericytomas account for less than 1% of all primary tumors of the central nervous system. Due to the lack of data available regarding this disease, national and international research provides information derived from retrospective case series and phase I and phase II studies. This is a case report of a young adult diagnosed with intracranial hemangiopericytoma in 2012 with a history of multiple recurrences and therapeutic approaches, assisted in a public health center in southeastern Brazil. Among the treatment options given to the patient, there are surgery, radiotherapy, and systemic chemotherapy (including alkylating and anthracyclines agents). Systemic therapy usually is offered after multiple recurrences or in a metastatic setting; although it increases progression-free survival, there is not enough data on objective response rate and does not yield increased overall survival.

---

## Introduction

Cancer is a non-transmissible disease considered as the second leading cause of death worldwide (approximately 21%) [1]. For 2019, 600 thousand new cancer cases were expected in Brazil [1].

Hemangiopericytomas are rare mesenchymal tumors originating from pericytes' proliferation and characterized by a distinguished biological and clinical behavior. They account for less than 1% of intracranial tumors [2], with an incidence of 3.77 / 10.000.000 [3] and are classified as soft tissue sarcomas and usually affect individuals between 20 and 70 years of age [4].

Incidence and prevalence data of malignant neoplasms in Brazil are usually presented biannually by José Alencar Gomes da Silva National Cancer Institute (INCA) [5]. However, due to underreported cases and a heterogenous distribution of cancer types among Brazilian regions, an accurate data regarding Brazil's cancer incidence and prevalence still is not available. Corroborating with these facts, INCA's Estimates 2018 book does not contain data on the prevalence and incidence of soft tissue tumors.

Therefore, this study aims to report a case of a young adult with intracranial hemangiopericytoma, a rare malignant neoplasm, with fewer descriptions on national and international literature, since its' treatment is based on results of case reports like this one.

## Case Report

This case report, which was accepted on the ethics committee under the registration number: CAAE 33375120.6.0000.9028, was about a patient of 22-year-old male with prior tumor excision in

the left hemiface (with orbital invasion) in 2012 and an anatomopathological result of fusocellular neoplasia. During this period, he was not assessed by a clinical oncologist and no additional treatment was performed.

About 5 years later, in 2017, he presented with an episode of severe headache and vomiting, refractory to medication. A new investigation was initiated, which detected an extensive tumor recurrence. Head computed tomography (Figure 1) scan showed a lesion of 7.9 x 8.4 x 9.3 cm, located in the middle fossa and infratemporal fossa on the left with contralateral midline deviation. After diagnosis, he underwent tumor embolization and partial excision in July 2017; the anatomopathological report came as a mesenchymal neoplasia and the hypotheses of sarcoma and hemangiopericytoma/malignant solitary fibrous tumor were questioned.

**Figure 1: 2017 RT Planning Image.**

An immunohistochemistry of the first surgical specimen (2012) was requested, which came positively for the STAT6 markers, favoring the diagnosis of hemangiopericytoma; other markers included ERG, p63, desmin, AML, HMB45, CD34, S100, AE1AE3, which were all negative.

In August 2017, he started external beam radiotherapy (60 Gy/30 fractions) and chemotherapy with doxorubicin at a dose of 50mg /m<sup>2</sup> every 21 days (total of 9 cycles - maximum dosage).

Clinical assessment during and after treatment indicated a partial response, with a residual tumor of 4.9 x 6.7 x 4.5 cm (contained by the dura mater), which was centered on the left sphenoid bone and extended to the middle cranial fossa, without invasion of the cerebral parenchyma or mass effect on the temporal lobe.

At the end of chemotherapy, he remained in clinical follow-up with Oncology and Neurology. After 18 months, he presented with episodes of massive epistaxis and maxillary sinusitis. A brain magnetic resonance imaging identified a bulky expansive and infiltrative lesion roughly measuring 5.7 x 4.5 x 4.8 cm, centered on the left hemiface, predominantly in nasal meatus on this side, with invasion of the maxillary sinus, nasopharynx, middle cranial fossa, cavernous sinus and turkish saddle. Tumor invaded adjacent bone structures with apparent destruction on the left side (nasal septum, septa of ethmoidal cells and left maxillary sinus walls); additionally, it was involving the carotid arteries at the intracavernous portions.

Subject underwent a new surgical approach by both Otorhinolaryngology and Head and Neck surgical teams. The surgery consisted in a left subtotal maxillectomy, left ethmoidectomy with resection of the middle concha and papyraceous lamina and sphenoidectomy for tumor resection by means of mediofacial Hemidegloving access. An exploration of the left pterygopalatine and infratemporal fossa was performed, as well as the exposure of the internal carotid artery, which was preserved. There was no major bleeding or surgical complications. After recovery, patient was again referred to consolidation radiotherapy and the resected piece was sent to the anatomopathological.

Although he was referred to consolidation radiotherapy, for personal reasons, patient did not attend the appointed consults or the scheduled radiotherapy sessions. He remained on clinical follow-up. The latest head and facial computed tomography scan (done 4 months after surgery), Figure 2, showed a hypodense, irregular amorphous area partially delimited, located posterolateral to the left orbit, measuring approximately 3.6 x 3.1 x 2.7 cm, with an estimated volume of 15.6 cm<sup>3</sup>. Such lesion invades the left orbit and touches the corresponding eyeball and lateral rectus muscle, without a well-defined cleavage plane with these structures.

**Figure 2: Skull MRI of Tumor Recurrence in 2019.**

On the latest clinical appointment (February 2020), patient was considered clinically stable, despite having left amaurosis and being partially dependent for daily-life activities. Pain management included methadone (10mg 3 times a day) and amitriptyline (50mg per day).

## Discussion

The first description of hemangiopericytoma occurred in 1942, when Stout and Murray identified tumors that derived from Zimmermann's pericytes [6]. The first intracranial case was published only in 1954 by Begg and Garret (1954) [7].

The solitary fibrous tumor and the hemangiopericytoma share similar histopathological characteristics and are now classified as a single biological entity. Both tumors have a NAB2-STAT6 fusion, regardless of the anatomical location (pleura, meninges or soft tissues) [8]. The fusion of the NAB2 and STAT6 genes generates nuclear expression of STAT6 (detected in immunohistochemistry) [9]. This characteristic is fundamental for a correct diagnosis of this pathology, being the reason why is analyzed in all suspected cases. In a normal genome, NAB2 and STAT6 are adjacent genes on chromosome 12q13 and are transcribed in opposite directions. In a fibrous tumor, however, chromosomal inversion occurs, fusing these two genes in the same direction of transcription [8]. From this fusion, stimulation of several growth factors and greater expression of tyrosine kinase receptors occurs, inducing tumor growth.

The most common sites of involvement of these tumors include lower limbs, retroperitoneum/pelvis, lung/pleura and meninges [9]. The symptoms of hemangiopericytoma include headache, dizziness, vomiting, asthenia and blurred vision. Additional signs may appear on physical examination, such as papilledema, hemiparesis, ataxia and other focal neurological deficits [10].

Due to its rarity, there is no standard treatment [10]. Published data on hemangiopericytoma are scarce and the ones currently available are based only on case reports and retrospective analyzes regarding treatment and tumor biological behavior.

Primary complete surgical resection is the consensual treatment for localized disease; it is the only treatment modality related to an increased overall survival [10] – reaching a 100% five-year overall survival, independently of tumor primary site [11] and up to an 89% ten-year overall survival [12]. However, intracranial tumors have higher rates of local and distant recurrence [13]

– approximately 43% and 15%, respectively [14]. Preoperative tumor embolization may be considered as a measure of reducing the risk of bleeding during surgery, since these types of cancer have a large vascularization [10].

Regarding adjuvant radiotherapy, the retrospective analysis published that described 17 patients with intracranial hemangiopericytoma, treated between 1995 and 2014 [15]. All patients underwent initial surgical treatment and 9 required re-approaches; no patient had distant metastasis. Adjuvant radiotherapy was administered to 16 patients regardless of the resection pattern (total or partial) with a median of 57.57 Gy/33 fractions. Among those analyzed, no patient received adjuvant chemotherapy. The median progression-free survival was 51 months and the median overall survival was not reached.

Another study by Patel et al (2017) carried out a retrospective analysis of 20 patients with hemangiopericytomas with a mean age of 45.6 years, assisted between 1985 and 2014 demonstrated that headache, visual disturbances and seizures were among the most common reported symptoms. Treatment focused mainly on surgical resection followed by adjuvant radiotherapy. The use of systemic chemotherapy was considered in cases of multiple recurrences. It was also pointed out that despite advances in surgical and radiotherapy techniques, these tumors

continue to have high recurrence rates and require adequate followup [13]. Management of recurrent and metastatic disease is not well established and that a complete surgical resection does not eliminate the risk of local tumor recurrence (commonly in the same surgical bed) [10].

From all studied and currently available treatment options for hemangiopericytomas, there is monoclonal antibodies, mTOR inhibitors, tyrosine kinase inhibitors, target therapies and the use of cytotoxic chemotherapy.

However, most published data are derived from case series, phase 1 and phase 2 studies, making it difficult for Oncologists to establish a standard therapy. In addition, part of the studies included patients with various types of soft tissue sarcomas and not solely hemangiopericytomas. In this context, the progression-free survival and overall survival rates reported in these studies are low, such as the use of temozolamide and bevacizumab (median 10.8 months and 24.3 months, respectively) [16]. For sunitinib, the median duration of treatment was 6 months [17] and for sorafenib, the medians for progression-free survival and overall survival were 3 and 17 months, respectively [18]. Pazopanib produced similar results, with a median progression-free survival of 4.7 months and median overall survival of 13.3 months [19]. Regarding the use of mTOR and IGF-1 inhibitors (analyzed after at least 2 lines of treatment), the results were disappointing [20]. It is necessary to keep in mind that there are no comparative efficacy data of those drugs in relation to the systemic chemotherapy regimens currently used such as anthracyclines.

Regarding chemotherapy, a retrospective study by Park et al (2013), showed the effectiveness in 21 patients assisted at the MD Anderson Cancer Center between 1994 and 2007. All subjects had measurable and advanced disease (unresectable, metastatic or potentially resectable) as a prerequisite for treatment. Among the chemotherapy regimens used, those based on doxorubicin were the majority (60%). Others included gemcitabine with docetaxel and paclitaxel. It is worth mentioning that 4 patients received more than 01 treatment regimen. Best objective response rate was stable disease and there was no complete or partial response. Median progression-free survival was 4.6 months and median overall survival was 10.3 years since diagnosis.

## Final Considerations

Hemangiopericytomas of the central nervous system are rare neoplasms with unpredictable behavior. In the absence of randomized clinical trials and large-scale studies, the only source of information on its natural history and clinical management is available from isolated case series.

In this context and based on what is currently published, surgical treatment associated with radiotherapy is valued to achieve better therapeutic efficacy. Conventional chemotherapy is effective in stabilizing locally advanced or metastatic disease and despite having minimal response rates (partial or complete clinical response), the clinical benefit achieved by reducing symptoms and stabilizing the disease justify its use in medical practice.
