Abstract

Aims: To evaluate the impact of the COVID-19 pandemic on breast cancer presentation, surgical management, and lymph node involvement in a small, understudied population in Brčko District, Bosnia and Herzegovina. **Methods:** A retrospective cohort study conducted at the General Hospital of Brčko District, Bosnia and Herzegovina, from March 2018 to March 2022. We included 113 patients with histopathologically confirmed breast cancer. We divided the patients into two groups: the before-COVID group (65 patients, including one male) treated from March 2018 to March 2020, and the during-COVID group (47 patients) treated from March 2020 to March 2022. We analyzed patient data (age, gender, menopausal status) along with tumor and lymph node histopathological characteristics. **Results:** The number of surgeries performed decreased by 16.9% during the COVID period. Patients in the pre-COVID group mostly had grade II tumors, while those in the post-COVID group had predominantly grade III tumors. The average number of lymph nodes sampled was similar between groups (10.70 ± 4.12 before COVID vs. 10.39 ± 4.66 during COVID). Still, the average number of positive lymph nodes was higher in the COVID group (2.5 ± 3.82) compared to the pre-COVID group (1.64 ± 2.90). For patients without neoadjuvant therapy, the average time to surgery increased from 1.04 months (± 0.66) before the COVID-19 pandemic to 2.59 months (± 2.88) during the COVID-19 pandemic. For those receiving neoadjuvant therapy, time to surgery increased from 5.45 months (± 2.97) to 7.29 months (± 5.15). **Conclusion:** The COVID-19 pandemic led to delayed breast cancer management, higher tumor grade, and increased lymph node involvement in a small, resource-limited healthcare setting. Findings highlight the need for resilient oncology services in smaller districts during public health crises.

Introduction

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was first identified in patients in Wuhan, Hubei Province, in December 2019 [1]. The World Health Organization (WHO) declared the disease caused by this virus to be coronavirus disease 2019 (COVID-19). According to WHO data, as of early February 2021, COVID-19 had caused over 2.2 million deaths and 103 million confirmed cases worldwide [2].

Breast cancer is the most commonly diagnosed cancer globally, with an estimated 2.3 million new cases annually. It represents a significant public health burden,

requiring enhanced efforts in both primary and secondary prevention worldwide [3]. Delayed diagnosis has resulted in breast cancers detected after quarantine exhibiting worse prognoses, with larger tumor sizes and higher rates of nodal involvement. This suggests that, during potential future lockdowns, breast cancer screening and follow-up examinations should continue without interruption, and patients should be encouraged to seek medical attention promptly if clinical symptoms arise [5]. The full impact of the COVID-19 pandemic on global oncology remains to be seen. Countries with high SARS-CoV-2 prevalence

and limited healthcare infrastructure are expected to experience more profound effects [6].

Several studies have reported a substantial impact of the COVID-19 pandemic on breast cancer care, including the suspension of screening programs [4-9]. For example, in Canada, the Netherlands, Germany, Italy, the United Kingdom, and Australia, national screening programs were suspended for periods ranging from one to six months [4]. However, data from small regional hospitals and underrepresented areas are scarce. The Brčko District in Bosnia and Herzegovina represents a small healthcare setting with limited oncology resources, where treatment delays, diagnostic constraints, and capacity limitations may have uniquely influenced patient outcomes.

This study aimed to evaluate the impact of the COVID-19 pandemic on breast cancer management in this small, understudied population. Unlike previous studies from large tertiary centers, our work captures real-world challenges in a small hospital, highlighting the clinical consequences of delays and resource limitations during a global pandemic. These findings can inform regional healthcare planning, prioritization of oncology care, and strategies to mitigate the impact of future crises.

Materials and Methods

This retrospective cohort study was conducted at Brčko District General Hospital, Bosnia and Herzegovina, between March 2018 and March 2022. March was chosen as the starting point to ensure two full years before and two years after the first confirmed case of COVID-19 in Bosnia and Herzegovina, which was registered in March 2020. The study included 113 female patients who underwent surgical treatment for histopathologically confirmed primary breast cancer. Diagnosis was established through imaging, including mammography, ultrasound, or breast MRI, and confirmed either by core biopsy or intraoperative ex tempore analysis following review by the multidisciplinary oncology council. Patients with stage IV disease not eligible for surgery, those requiring subcutaneous mastectomy with reconstruction, and those with incomplete medical records or missing histopathological data were excluded. Demographic, clinical, and tumor-related data were extracted from electronic and paper-based hospital records and independently verified by two investigators to ensure accuracy.

Patient characteristics included age, menopausal status, and comorbidities. Tumor characteristics encompassed tumor size, histological type, receptor status (ER, PR, HER2), Ki-67 proliferation index, histological grade, clinical TNM stage, and number of positive axillary lymph nodes. Primary outcomes were histological grade, axillary lymph node involvement, and time from diagnosis to surgery, while secondary outcomes included type of surgical procedure performed, use of neoadjuvant therapy, and Ki-67 index. Subgroup analyses were performed based on age, menopausal status, and molecular subtype where appropriate.

All patients underwent standardized preoperative

evaluation, including clinical examination, imaging, laboratory tests (complete blood count, biochemistry, tumor markers CEA, CA 15-3, and CA 125), and additional staging investigations such as chest X-ray, skeletal survey, CT scans, and abdominal ultrasound when indicated. Internal medicine and anesthesiology assessments ensured surgical eligibility under general anesthesia. Treatment decisions were made by the oncology council. Neoadjuvant therapy was administered to patients with palpable axillary lymph nodes, tumor size greater than 2 cm, triple-negative or HER2-positive tumors, high Ki-67 index, unresectable tumors, or inflammatory carcinoma. Surgery was performed either after tumor downstaging or immediately in early-stage disease.

Surgical procedures included radical and simple mastectomy, partial breast resection with sentinel lymph node biopsy, axillary dissection, and tumorectomy. Sentinel lymph nodes were identified using 0.5 ml of subdermal methylene blue in the periareolar region and sent for ex tempore analysis; positive nodes prompted axillary dissection. Tumor excision aimed for negative margins, confirmed intraoperatively. Extent of surgery followed TNM staging guidelines, and definitive histopathology guided adjuvant therapy recommendations. All patients were screened for SARS-CoV-2 using rapid immunochromatographic tests prior to admission, and only those testing negative were admitted for surgery. Oncology patients were prioritized for surgery during pandemic-related capacity limitations.

Continuous variables were summarized as mean $\pm$ standard deviation or median with range, and categorical variables as counts and percentages. Between-group comparisons were performed using Student's t-test or Mann-Whitney U test for continuous variables and chi-square or Fisher's exact test for categorical variables. Multivariate logistic regression was conducted to identify independent predictors of higher histological grade and lymph node positivity, adjusting for age, tumor size, and receptor status. Statistical significance was defined as $p \leq 0.05$. Analyses were performed using SPSS version 24 and JASP version 0.16.

Results

The total number of patients in the pre-COVID group was 66 (58.4%), while in the during-COVID group it was 47 (41.5%). The number of surgeries performed during the COVID period decreased by 16.9%. The average age of patients before the COVID-19 pandemic was 62.02 years (SD = 11.97), and during the pandemic, it was 61.96 years (SD = 12.53) (Table 1).

Regarding neoadjuvant therapy, the absolute number of patients receiving it was the same ($n = 16$), but the proportion differed. Before the COVID-19 pandemic, 24.24% of patients received neoadjuvant therapy, compared to 34.04% during the pandemic, representing a 9.8% increase (Table 2). These results suggest that more advanced tumor stages occurred during the pandemic, although the difference was not statistically significant ($p = 0.254$).

Table 1. Characteristics of Patients in the Observed Groups

Observed Groups	Before COVID-19	During COVID-19
Number of patients	66 (58.4%)	47 (41.5%)
Average age (years)	62.02 (SD = 11.97)	61.96 (SD = 12.53)

Table 2. Neoadjuvant therapy and Chi-square Test

Neoadjuvant Therapy	Before COVID-19	During COVID-19	Chi-square Value	df	Significance (p)
YES	16 (24.24%)	16 (34.04%)	1.299	1	0.254
NO	50 (75.76%)	31 (65.96%)			
Total	66 (100%)	47 (100%)			

Table 3. Type of Surgical Procedures

Type of surgery	Before COVID-19 (%)	During COVID-19 (%)
Radical mastectomy	35 (53.03)	29 (61.70)
Simplex mastectomy	4 (6.06)	2 (4.26)
Partial breast resection with axillary dissection	17 (25.76)	4 (8.51)
Partial breast resection with SLNB	8 (12.12)	9 (19.15)
Partial breast resection	2 (3.03)	3 (6.38)
Total	66 (100)	47 (100)

Types of surgical procedures were similar before and during the pandemic ($p > 0.05$). Radical mastectomy was the most common surgery in both periods (53.03% vs. 61.70%) (Table 3).

Histological tumor grade showed significant differences (Figure 1). Before the COVID-19 pandemic, grade II tumors predominated (73.85%), followed by grade III (18.46%) and grade I (7.69%). During COVID, grade III tumors were most frequent (56.52%), followed by grade II (39.13%) and grade I (4.35%). These results indicate a shift towards more aggressive tumors during the pandemic.

Comparison between groups showed significantly more grade III tumors during COVID ($p < 0.05$) and more grade II tumors before COVID ($p < 0.001$).

Regarding axillary lymph nodes, the median number removed was similar between groups (10 vs. 12, $p = 0.357$), but the number of positive (metastatic) lymph nodes was

significantly higher during COVID (median one vs. 0, $p = 0.04$) (Table 4).

Ki-67 expression was higher before COVID, but this difference was not statistically significant ($p = 0.05$) (Figure 2).

Time from diagnosis to surgery increased during the pandemic. Among patients without neoadjuvant therapy, the mean time to surgery was 1.04 months before the COVID-19 pandemic and 2.59 months during the COVID-19 pandemic ($p = 0.05$). For patients receiving neoadjuvant therapy, the time increased from 5.45 to 7.29 months; however, this difference was not statistically significant ($p = 0.337$) (Tables 5 and 6).

Discussion

This study provides unique insights from a small regional hospital with limited oncology resources, a setting rarely represented in COVID-19 literature. Our study found a 16.8% reduction in breast cancer surgeries during the COVID-19 pandemic, consistent with other reports [7, 8]. These results likely reflect decreased hospital admissions and limitations in surgical capacity. Similar studies reported increased stage IV diagnoses and reduced surgery volumes during early pandemic months [7, 8].

The proportion of patients receiving neoadjuvant therapy increased by nearly 10% during the pandemic. However, this increase was not statistically significant, supporting the findings of Chapgar et al. and Corke et al., who observed an increase in the use of neoadjuvant therapy as a strategy to manage delays and surgical limitations [9, 10].

Axillary lymph node involvement was significantly higher during COVID-19, confirming more advanced disease at presentation, a critical prognostic factor associated with recurrence risk and survival [11, 12].

Figure 1. Distribution of Histological Tumor Grades before and During COVID-19.

Table 4. Axillary Lymph Node Status

Status of Axillary Lymph Node	Before COVID-19	During COVID-19	p value
Axillary lymph nodes removed	Median: 10 (range 6–22)	Median: 12 (range 6–19)	0.3565
Positive axillary lymph nodes	Median: 0 (range 0–10)	Median: 1 (range 0–14)	0.04 (*)

(*) The difference was statistically significant

Figure 2. Ki-67 Expression before and During COVID-19.

This trend aligns with the observed increase in high histological grade tumors during the pandemic, suggesting a shift toward more aggressive disease [13, 14].

Although Ki-67 is a recognized marker of tumor proliferation and worse prognosis [15], we did not find significant differences in its expression before and during the pandemic.

We observed prolonged time to surgery during the pandemic, especially in patients without neoadjuvant therapy. This delay may contribute to tumor progression and worse outcomes, as also reported in other studies [16, 17].

Our study has several limitations: we used a retrospective design, enrolled a relatively small sample, and did not collect data on radiation therapy or all surgical procedures (e.g., subcutaneous mastectomy, which our institution does not perform).

In conclusion, the COVID-19 pandemic negatively impacted breast cancer management in the Brčko District, with patients presenting with more advanced and aggressive tumors, increased lymph node involvement, higher neoadjuvant therapy use, and longer delays to surgery. These findings underscore the importance of maintaining timely cancer care even during public health crises. Findings underscore the importance of maintaining timely oncology care in small, resource-limited hospitals during public health emergencies.
